Gender Differences in Educational and Occupational Patterns Among the Gifted

Jacquelynne S. Eccles & Rena D. Harold
University of Colorado & Michigan State University

Despite recent efforts to increase the participation of women in advanced educational training and high status professional fields, women in general, and gifted women in particular, are still underrepresented in many fields, particularly those associated with technology, physics, and applied mathematics. The fact that gifted women are underrepresented in these fields is especially worrisome since these women clearly have sufficient intellectual talent to participate as fully as their male peers in these educational and vocational settings. Many factors contribute to this discrepancy, not all of which can be discussed in a single talk. Today we will focus on a set of social and psychological factors that we and our colleagues have been studying for the last 20 years. We'll begin with a brief review of the sex differences in educational and occupational patterns among the gifted. We will then summarize a model to account for these differences, review the available evidence to support the hypotheses generated by the model, and discuss the role socialization agents may be playing in perpetuating these sex differences.

In reviewing the educational and occupational patterns of gifted men and women, we have relied heavily on two sets of data: the longitudinal data compiled on Terman's gifted population and the cross-sectional and longitudinal data being compiled by researchers associated with the Study of Mathematically Precocious Youth originally based at Johns Hopkins University.

Terman's Gifted Population

In 1921, Terman began a longitudinal study of approximately 1,450 gifted boys and girls 7 to 15 years old. The original sample contained 831 males and 613 females. These individuals have been interviewed several times; extensive demographic, intellectual, and social-developmental data were gathered at each contact. Because the researchers have been able to relocate approximately 80 percent of the original sample at each new wave of data collection, this longitudinal study provides the richest and most complete set of data available on the life-span development of gifted males and females. Although bound by its historical period, it provides the best data available for comparing the educational and occupational patterns of gifted males and females.

Sex differences in the educational and occupational patterns of Terman's sample first emerged when the sample was in college. As is apparent from the data in Table 1, these men and women chose to study very different fields at both the graduate and undergraduate level (Terman & Oden, 1947), in particular, with relation to physical science and engineering. As can be seen in Table 2, there were also substantial differences in the amount of education obtained by the females and males in this study. While the men and women were equally likely to earn their bachelor's degree, the men were more likely than the women to complete graduate degrees.

Differences in occupational patterns are even more extreme. The most striking difference lies in the proportion of men and women who reported having an occupation: the women were much less likely to be employed than the men during most of their adult years. These women and men also tended to be employed in sex-role stereotypic jobs (see Table 3). The women were especially likely to be underrepresented in high status jobs of all kinds, and in the fields of science and engineering, in particular. They were overrepresented in the fields of precollege
teaching and social welfare. Clearly these gifted women achieved less than their gifted male peers in terms of educational and occupational advancement.

Johns Hopkins Study of the Gifted

Over the past 20 years, Julian Stanley, Camilla Benbow, and their colleagues at Johns Hopkins University have been studying mathematically and verbally precocious children. During this period, several thousand junior high school-aged children drawn from regional and national talent searches have been given aptitude tests and questionnaires tapping attitudes, career plans, interests, and values. Many of these children have been or are currently being retested in order to chart their educational development.

One of the most interesting aspects of the data emerging from these studies is their similarity to the findings of the Terman studies, especially given the social changes that have occurred during the last 50 years. Just as was true in the Terman study, fewer females than males have emerged as gifted in mathematics in each of the Johns Hopkins studies. Furthermore, the boys in the Johns Hopkins samples have consistently scored higher than the females on the SAT-Math test (the test used by the Johns Hopkins team to assess mathematical talent). Finally,
the girls have scored as well as the boys on the SAT-Verbal test (the test used to assess verbal talent). Thus, as was true of the Terman sample, giftedness in math is more common and more extreme among boys. In contrast, verbal precocity appears more equally distributed between the sexes (Fox & Cohn, 1980).

Note: Percentages based on number of full-time employed individuals within each sex. Data are based on Oden, 1968 and reflect employment status in 1960. Total population in 1960: males 759; females 597. Total number and percent employed: males 738 (96%); females 253 (42%).

The pattern of sex differences in educational pursuits is also quite similar across the two studies despite the lapse of 50 years. In fact, differences that were not apparent until college in the Terman sample are evident in the Johns Hopkins samples by junior high school. This difference is best characterized in terms of the under-representation of girls in 'extra' educational settings, especially settings associated with math and science. The Johns Hopkins teams have consistently found that gifted girls were less likely than gifted boys to be enrolled in accelerated and/or special programs (Benbow & Stanley, 1982; Stanley, 1976), to respond positively to an invitation to join a gifted program (George & Denham, 1976; Stanley, 1976), and to enter college early (Stanley, 1976). In addition, in follow-ups of the boys and girls who enrolled in the Johns Hopkins Summer Enrichment courses, the girls were less likely to remain on an accelerated math track (Fox & Cohn, 1980). Finally, as in clear in Table 4, the girls identified by the various talent searches enrolled in fewer physics courses (Benbow & Stanley, 1982; Benbow & Minor, 1986), were less likely to take AP courses in the sciences and less likely to take
advanced placement exams or college board achievement tests in chemistry and physics (Benbow & Minor, 1986), expressed less interest in majoring in science or engineering in college than the boys (Benbow & Stanley, 1984) and reported liking physics and chemistry less in high school (Benbow & Minor, 1986). The females were also significantly less likely to major in the physical sciences and engineering in college, to seek post graduate training in physics, computer science, and engineering, and to aspire to a career in physical science and engineering, particularly a research career in these fields (Benbow, 1988). These differences exist despite the fact that these girls, like the girls in the Terman study, did just as well as the boys in their high school math and science courses.

<sup>1</sup> The number of individuals was calculated based on information provided in the Benbow and Minor, 1986 article.

<sup>2</sup> These percentages come from Benbow and Minor, 1986 and Benbow, 1988.

<sup>3</sup> Sex difference primarily due to differences in physics, computer science, and engineering.

Conclusions

As is true for the population at large (Eccles Parsons, 1984), gifted females do not achieve as much as gifted males do in terms of educational and vocational advancement. They are less likely to seek out advanced educational training, and, even when they do, they do not enter the same fields as do their male peers. They are overrepresented in educational and literary fields, and underrepresented in science, math, and engineering. But most importantly, they are, in fact, underrepresented in almost all advanced educational programs and in the vast majority
of high status occupations. Gifted women are less likely to have a professional career than their male peers. And even those who choose to have a profession tend to select occupations that have lower status, require less education, are more compatible with family time schedules, and make fewer demands on one's off-the-job time and on one's family. Similar results have emerged in other recent longitudinal studies of gifted females, although these women have fared relatively better than the women in the Terman sample (Card, Steele, & Abeles; 1980, Kaufmann, 1981; Kerr, 1985; Rodenstien & Glickhauf-Hughes, 1979). And those gifted women who do achieve at high levels are less likely to be married and to have children, and if they have children, they tend to have fewer children than their gifted male peers.

One might argue that the underrepresentation of females in the sciences is a natural consequence of the pattern of sex differences on the aptitude measures taken by both Terman and the Johns Hopkins team. This is an unwarranted conclusion for several reasons. First, both of these studies focused on gifted children. Thus, even though the females may have less math aptitude than their male peers, they certainly have sufficient aptitude to become important contributors to scientific, as well as other, professions. The critical question was pointed out by Lila Braine (1988) in her response to Benbow's 1988 article in *Brain and Behavioral Science* - to quote "Why are women virtually absent from fields for which they clearly have the requisite math skills?" Second, while aptitude differences were positively related to the subsequent mathematical training of gifted boys in the Johns Hopkins programs, aptitudinal differences were unrelated to the gifted girls' decisions regarding both enrollment in subsequent accelerated math classes (Fox & Cohn, 1980) and intended college major (Benbow & Stanley, 1984). Furthermore, the sex differences in high school physics enrollment and in intended college major were significant even when the differences in math aptitude were statistically controlled (Benbow & Stanley, 1982, 1984; Benbow & Minor, 1986; Benbow, 1988).

Given these concerns, it is quite likely that social forces and personal beliefs play a significant role in perpetuating the sex differences in the sex-differentiated educational and vocational patterns of gifted individuals. And, although institutional barriers and discriminatory practices undoubtedly account for some of the differences, psychological processes are also important (see Astin, 1984; Bell, 1989; Dweck & Licht, 1980; Eccles Parsons, 1984; Eccles & Hoffman, 1984; Farmer, 1985; Friese & Hanusa, 1984; Helson, 1980; Humphreys, 1984; Huston, 1983; Kerr, 1985; Nash, 1979). These processes are the focus of the remainder of this talk.

**Psychological Influences on Educational and Vocational Choices:**

**A Model of Achievement-Related Choices**

Over the past 20 years, my colleagues and I have studied the motivational and social factors influencing such long and short range achievement goals and behaviors as career aspirations, vocational and avocational choices, course selections, persistence on difficult tasks, and the allocation of effort across various achievement-related activities (see Eccles, Adler, Futterman, Goff, Kaczala, Meece, & Midgley, 1983; Meece, et al., 1982). Given the striking differences in the educational and vocational patterns of both intellectually able and gifted males and females, we have been particularly interested in the motivational factors underlying males' and females' educational and vocational decisions. Frustrated with the number of seemingly disconnected theories proliferating to explain sex differences in these achievement patterns, we developed a comprehensive theoretical framework to guide our research endeavor. Drawing upon the theoretical and empirical work associated with decision-making, achievement theory, and attribution theory (see Atkinson, 1964; Crandall, 1969; Weiner, 1974), we have elaborated a model of achievement-related choices. This model, depicted in Figure 1, links educational, vocational, and other achievement-related choices most directly to two sets of beliefs: the individual's expectations for success and the importance or value the individual attaches to the various options perceived by the individual as available. The model also specifies the relation of these beliefs to cultural norms, experiences, aptitudes, and to those personal beliefs and attitudes that
are commonly assumed to be associated with achievement-related activities by researchers in this field (Eccles et al., 1983). In particular, the model links achievement-related beliefs, outcomes, and goals to causal attributional patterns, to the input of socializers (primarily parents and teachers), to gender-role beliefs, to self perceptions and self concept, and to one's perceptions of the task itself. Each of these factors is assumed to influence both the expectations one holds for future success at the various achievement-related options, and the subjective value one attaches to these various options. These expectations and the value attached to the various options, in turn, are assumed to influence choice among these options.

![Diagram](image-url)

**Figure 1.**

For example, let us consider course enrollment decisions. The model predicts that people will be most likely to enroll in courses that they think they will do well in and that have high task value for them. Expectations for success depend on the confidence the individual has in his/her intellectual abilities and on the individual's estimations of the difficulty of the course. These beliefs have been shaped over time by the individual's experiences with the subject matter and by the individual's subjective interpretation of those experiences (e.g., does the person think that her/his successes are a consequence of high ability or lots of hard work?). The value of a particular course is also influenced by several factors including the following: Does the person like doing the subject material?; Is the course required?; Is the course seen as instrumental in meeting one of the individual's long or short range goals?; Have the individual's parents or counselors insisted that the course be taken or, conversely, have other people tried to discourage the individual from taking the course?; Is the person afraid of the material to be covered in the course?

Three features of our model are particularly important for understanding sex differences in the educational and vocational decisions of gifted individuals: The first of these is our focus on achievement-related choices as the outcome of interest. We believe that individuals continually make choices, both consciously and nonconsciously,
regarding how they will spend their time and their efforts. Many of the most significant sex differences among the gifted (e.g., vocational aspirations) occur on achievement-related behaviors that involve the element of choice, even if the outcome of that choice is heavily influenced by socialization pressures and cultural norms. Conceptualizing sex differences in achievement patterns in terms of choice takes one beyond the question of "Why aren't gifted women more like gifted men?" to the question "Why do gifted women and men make the choices they do?". Asking this latter question, in turn, legitimizes the choices both gifted men and women make and suggests several new variables as possible mediators of the sex differences we observe in gifted individuals' achievement patterns. By legitimizing the choices of both men and women, it allows us to look at the sex differences from a choice perspective rather than a deficit perspective.

Conceptualizing sex differences in achievement-related behaviors in terms of choice highlights a second important component of our perspective; namely, the issue of what becomes a part of an individual's field of possible choices. Although individuals do choose from among several options, they do not actively, or consciously, consider the full range of objectively available options in making their selections. Many options are never considered because the individual is unaware of their existence. Other options are not seriously considered because the individual has inaccurate information regarding either the option itself or the individual's possibility of achieving the option. For example, a girl may have inaccurate information regarding the full range of activities an engineer can do or inaccurate information regarding the financial assistance available for advanced educational training. Still other options may not be seriously considered because they do not fit with the individual's gender-role schema. Assimilation of the culturally defined gender-role schema can have such a powerful effect on one's view of the world that activities classified as part of the opposite sex's role are rejected, often nonconsciously, without any serious evaluation or consideration (c.f. Huston, 1983; Kerr, 1985; Nash, 1979).

Understanding the processes shaping individuals' perceptions of their field of viable options is essential to our understanding of the dynamics leading gifted men and women to make such different achievement-related decisions. Yet there is very little evidence regarding these processes and their link to important achievement-related choices. Socialization theory provides a rich source of hypotheses; few of which have been tested in gifted populations. For example, one effect of role models may be to legitimize novel and/or sex-role deviant options. Parents, teachers, and school counselors can also influence students' perceptions of their field of options through the information and experiences they provide the students regarding various options. Finally, peers can affect the options seriously considered by either providing or withholding support for various alternatives. These peer effects can be both quite direct (e.g., laughing at a girl when she says she is considering becoming a nuclear physicist), and very indirect (e.g., anticipation of one's future spouse's support for one's occupational commitments) (for examples of these see Bell, 1989; Kerr, 1985).

The third important feature of our perspective is the explicit assumption that achievement-related decisions, such as the decision to enroll in an accelerated math program or to major in education rather than engineering, are made within the context of a complex social reality that presents each individual with a wide variety of choices; each of which has both long range and immediate consequences. Furthermore, the choice is often between two or more positive options or between two or more options that each have both positive and negative components. For example, the decision to enroll in a physics course is typically made in the context of other important decisions such as whether to take advanced English or a second foreign language, whether to take a course with one's best friend or not, whether it's more important to spend one's senior year working hard or having fun, etc. Too often theorists have focused attention on the reasons why gifted, capable women do not select the high status achievement options and have failed to ask why they select the options they do. This approach implicitly assumes that complex choices, such as career and course selection, are made in isolation of one another; for example, it is assumed that the decision
to take advanced math is based primarily on variables related to math. We explicitly reject this assumption, arguing instead that it is essential to understand the psychological meaning of the roads taken as well as the roads not taken if we are to understand the dynamics leading to the differences in men's and women's achievement-related choice (c.f., Kerr, 1985).

Consider, as an example, two gifted high school students: Mary and Barbara. Both young women enjoy mathematics and have always done very well. Both have been identified as gifted in mathematics and have been offered the opportunity to participate in an accelerated math program at the local college during the next school year. Barbara hopes to major in journalism when she gets to college and has also been offered the opportunity to work part time on the city newspaper doing odd jobs and some copy editing. Mary hopes to major in biology in college and plans a career as a research scientist. Taking the accelerated math course involves driving to and from the college. Since the course is scheduled for the last period of the day, it will take the last two periods of the day as well as one hour of after-school time to take the course. What will the young women do? It all likelihood, Mary will enroll in the program because she both likes math and thinks that the effort required to take the class and master the material is worthwhile and important for her long range career goals. Barbara’s decision is more complex. She may want to take the class but may also think that the time required is too costly, especially given her alternative opportunity at the city paper. Whether she takes the college course or not will depend a lot on the advice she gets at home and from her counselors. If they stress the importance of the math course then its subjective worth to her will increase. If its subjective worth increases sufficiently to outweigh its subjective cost, then Barbara will probably take the course despite its cost in time and effort.

In summary, we assume that achievement-related choices are guided by the following: (a) one’s expectations for success on the various options, (b) the relation of the options both to one’s short and long range goals and to one’s core self identity and basic psychological needs, (c) the individual’s gender-role schemas, and (d) the potential cost of investing time in one activity rather than another. All of these psychological variables are influenced by one’s experiences, by cultural norms, and by the behaviors and goals of one’s socializers and peers. Let me now discuss each of these variables in more detail as they relate to the achievement-related decisions of gifted men and women. It should be noted, however, that although there are sound theoretical reasons for suggesting these links, in most cases the essential empirical work remains to be done.

**Expectations for Success/Confidence in One’s Ability**

Expectations for success and confidence in one’s abilities to succeed have long been recognized by decision and achievement theorists as important mediators of behavioral choice (e.g. Atkinson, 1964; Bandura, 1977; Lewin, 1938; Nicholls, 1975; Weiner, 1974). There have been numerous studies demonstrating the link between expectations and a variety of achievement-related behaviors including educational and vocational choices among both average and gifted populations. For example, Hollinger (1983) documented a fairly strong relationship between gifted girls’ confidence in their math abilities and their aspirations to enter math-related vocations such as engineering and computer science. Similarly, Terman (1926) found a positive relationship between gifted students’ subject matter preferences and their ratings of the ease of the subject for themselves.

But do males and females differ in their expectations for success at various academic subjects and in various occupations? The answers to these questions are not clear. For example, Fox (1982) found that highly-motivated gifted girls have lower self-confidence than equally highly-motivated gifted boys; similarly, Terman (1926) found that gifted girls were more likely to underestimate their intellectual skills and knowledge while gifted boys were more likely to overestimate theirs. A recent study in New York City also found that gifted high school girls are more likely to underestimate their class standing and to report test anxiety than their gifted male peers (Strauss &
Similarly, in our own recent work, girls enrolled in a special gifted elementary school program rated their test anxiety higher than did their male peers in the same program. We had the fifty-five students enrolled in one southeastern Michigan public school district’s gifted elementary school program fill out a self-report questionnaire. This questionnaire included measures of the following constructs for the domains of math, reading, sport, and instrumental music: how good they thought they were in each domain, how much they enjoyed doing activities in each of these domains, how important it was to them to do well in each of these domains, how useful they felt what they were learning was in each of these domains, and how important they thought it was to their parents that they do well in each of these domains. We report the preliminary results of this study that were appropriate; the mean differences are summarized in Table 5.

</table>

Note: Items assessed on seven point Likert Scale with 7 equal high rating for construct as described in item indicators. N = 55 gifted children in grades 2, 3, and 5.

In contrast, several studies have found no sex differences on measures of general self-concept, locus of control (a construct often linked to self confidence and personal efficacy beliefs; e.g. Bandura, 1977), general self-confidence and assertiveness, and general self-esteem (Dauber & Benbow, 1990; Tidwell, 1980; Tomlinson-Keasey & Smith-Winberry, 1983). Furthermore, although the girls in our study of gifted elementary school children reported higher estimates for their reading ability than did the boys, the boys and girls reported equivalent confidence in their mathematical ability. Similarly, Benbow and Stanley (1982) found no substantial sex difference in gifted students' estimates of their math and science competence. And, although the gifted students in his study did prefer courses that they thought were easier for them, the boys and girls in Terman's study (1926) did not differ in their perceptions of the ease of mathematics. Finally, Schunk and Lilly (1982) found no sex difference in gifted children's expectations for success on a laboratory math task. There is even some recent data suggesting that gifted males are less confident and have lower self-esteem than gifted females during the elementary school and college years (Bartell & Reynolds, 1986; Tomlinson-Keasey & Smith-Winberry, 1983).

Given this mixed set of results, it is not clear that gifted girls are typically less confident of their intellectual abilities than are gifted boys. Although it is true that the differences, when they are found, do support
this conclusion, the differences, even when they exist, are quite small. Furthermore, the mediating role of these sex differences in explaining the sex differences in educational and vocational choices has not been demonstrated.

It is possible, however, that researchers have been assessing the wrong expectancies. Typically, the students are asked to report on their confidence about succeeding on an upcoming task or course. They are not asked how confident they are that they could succeed in particular professions or in particular advanced training programs. They are also not asked how much effort they think it will take to succeed in various professions or advanced training programs. It could be that gifted girls are less confident than gifted boys of their prospects for success in these more abstract, distant activities. It is also possible that gifted girls are as confident as gifted boys in their ability to succeed but assume that it will take a lot more effort to succeed than their male peers assume it will take (Kerr, 1985). As noted earlier, either of these beliefs could mediate a sex difference in the educational and vocational decisions of gifted individuals, especially given the gender stereotyping of high status occupations.

Finally, perhaps the critical comparisons are not gender comparisons within domain, but domain comparisons within gender. If individuals are more likely to pursue those activities that they are the most confident about, then it would be more important to determine whether females and males have different rank orderings for their self-concepts across an array of domains than to determine whether females and males differ in their self-concepts on any one particular domain. In our recent study, for example, we found that the girls had more confidence in their reading ability than in their math ability even though they did not have lower confidence in their math ability than their male peers. Clearly more research is needed before these hypotheses can be evaluated.

**Values as Mediators of Achievement-Related Choices**

Value is the second major component of our expectancy/value model of achievement-related choices. This model predicts that decisions regarding course enrollments, college majors, and occupational choices are influenced by the values individuals attach to the various achievement-related options they believe are available to them. Furthermore, subjective value is hypothesized to have at least as much influence as expectations for success on educational and vocational choices. Finally, given the probable impact of gender-role socialization on the variables assumed to be associated with subjective task value, sex differences in the subjective value of various achievement-related options are predicted to be important mediators of sex differences in achievement-related choices in both typical and gifted populations. Our own data support this hypothesis. In a longitudinal study of the math course enrollment decisions of high aptitude, college-bound students, sex differences in students' decisions to enroll in advanced mathematics were mediated primarily by sex differences in the value the students' attached to mathematics (Eccles, Adler, & Meece, 1984). More specifically, the girls were less likely than the boys to enroll in advanced mathematics primarily because they felt that math was less important, less useful, and less enjoyable than did the boys.

Since value means many things to different social scientists and since value has received so little systematic attention until recently, we would like to elaborate on our interpretation of value and its link to achievement-related choices before reviewing the empirical literature. Like others (e.g. Crandall, Katkovsky, & Preston, 1962; Raynor, 1974; Stein & Bailey, 1973), we assume that task value is a quality of the task that contributes to the increasing or declining probability that an individual will select it. We have defined this quality in terms of four components: (1) the utility value of the task in facilitating one's long range goals or in helping the individual obtain immediate or long range external rewards; (2) intrinsic interest in the task; (3) attainment value or the value an activity has because engaging in it is consistent with one's self-image; and (4) the cost of engaging in the activity. The last two of these are especially important for any consideration of the impact of gender roles on the value people attach to various activity choices. So let us say a little bit more about each of these.
Attainment value

We are conceptualizing attainment value in terms of the needs and personal values that an activity fulfills. As they grow up, individuals develop an image of who they are and what they would like to be. This image is made up of many component parts including (a) conceptions of one's personality and capabilities, (b) long range goals and plans, (c) schema regarding the proper roles of men and women, (d) instrumental and terminal values (Rokeach, 1973), (e) motivational sets, (f) ideal images of what one should be like; and (g) social scripts regarding proper behavior in a variety of situations. Those parts of an individual's self-image that are central or critical to self-definition should influence the value the individual attaches to various educational and vocational options; these differential values, in turn, should influence the individual's achievement-related choices (Eccles, Adler, & Meece, 1984; Markus, 1980; Parsons & Goff, 1980). For example, if helping other people is a central part of Individual B's image, then B should place higher value on "helping" occupations than on "non-helping" occupations.

Essentially, we are arguing that personal needs, self-images, and values operate in ways that both reduce the probability of engaging in those activities or roles perceived as inconsistent with one's central values and increase the probability of engaging in roles or activities perceived as consistent with one's definition of self. More specifically, we believe that individuals perceive tasks in terms of certain characteristics that can be related to their needs and values. For example, a difficult task requiring great effort for mastery may be perceived as an achievement task; if it also involves pitting one's performance against others, it may be perceived as a competitive task. Other tasks may be perceived in terms of nurturance, power, or aesthetic pleasure. Participating in a particular task will require the demonstration of the characteristics associated with the task. Whether this requirement is seen as an opportunity or a burden will depend on the individual's needs, motives, and personal values, and on the individual's desire to demonstrate these characteristics both to him/herself and to others (see Bell, 1989 and Kerr, 1985 for examples of these dynamics among the gifted).

In summary, we are assuming the following: (1) individuals seek to confirm their possession of those characteristics central to their self-image; (2) various tasks provide differential opportunities for such confirmation; (3) individuals place more value on those tasks that either provide the opportunity to fulfill their self-image or at least are consistent with their self-image and long range goals, and (4) individuals are more likely to select tasks with high subjective value than tasks with lower subjective value. To the extent that gifted males and females have different self-images, various activities will come to have different subjective value for gifted males and females. And, to the extent that gifted males and females place differential subjective value on various educational and vocational options, they should also differ in their educational and vocational choices. This hypothesis is discussed in more detail later.

Perceived Cost

The value of a task also depends on a set of beliefs that can best be characterized as the cost of participating in the activity. Cost is influenced by many factors, such as anticipated anxiety, fear of failure, and fear of the social consequences of success. Gender differences are quite likely on each of these psychological costs (e.g., see Bell, 1989; Eccles Parsons, 1984; Kerr, 1985). Cost can also be conceptualized in terms of the loss of time and energy for other activities. People have limited time and energy. They can not do everything they would like. They must choose among activities. To the extent that one loses time for Activity B by engaging in Activity A and to the extent that Activity B is high in one's hierarchy of importance, then the subjective cost of engaging in A increases. Alternatively, even if the attainment value of A is high, the value of engaging in A will be reduced to the extent that the attainment value of B is higher and to the extent that engaging in A jeopardizes the probability of successfully engaging in B (see Kerr, 1985 for good examples of this process in action in gifted women's lives).
Gender-Roles and Task Value

This analysis has a number of important implications for our understanding of sex differences in the educational and vocational choices of gifted individuals. Because socialization shapes individuals' goals and values, men and women should acquire different values and goals through the process of gender-role socialization. Through their potential impact on subjective task value, these gender differences in value structure can affect educational vocational choices in several ways.

For one, gender-role socialization could lead males and females to have different hierarchies of core personal values (such as their terminal and instrumental values, Rokeach, 1973). Consequently, tasks embodying various characteristics should have different subjective values for men and women. For example, both boys and girls stereotype mathematicians and scientists as loners who have little time for their families or friends because they work long hours in a laboratory on abstract problems that typically have limited immediate social implications (Boswell, 1979). If the analysis developed in the previous section is correct, such a profession should hold little appeal to someone who rates social values high and thinks it is very important to devote time and energy to one's family. Because gifted females rate social values higher than gifted males (Fox & Denham, 1974), gifted females should be less likely to aspire to a career as a mathematician or scientist than gifted males.

Several studies provide support for the hypothesized link between personal values and achievement-related choices. Dunteman, Wisenbaker, and Taylor (1978) studied the link between personal values and selection of one's college major using a longitudinal, correlational design. They identified two sets of values both that predicted students' subsequent choice of major and differentiated the sexes: the first set (labeled thing-orientation) reflected an interest in manipulating objects and understanding the physical world; the second set (labeled person-orientation) reflected an interest in understanding human social interaction and a concern with helping people. Students who were high on thing-orientation and low on person-orientation were more likely than other students to select a math or a science major. Not surprisingly, females in their study were more likely than males to be person-oriented and to major in something other than math or science; in contrast, the males were more likely than the females both to be thing-oriented and to major in math and science.

Men and women could also differ in the density of their goals and values. There is some evidence suggesting that men are more likely than women to exhibit a single-minded devotion to one particular goal, especially their occupational goal. In contrast, women in both gifted and average ability populations seem more likely than men to be involved in, and to value, competence in several activities simultaneously (Baruch, Barnett, & Rivers, 1983; Bell, 1989; Fox, Pasternak, & Peiser, 1976; Kerr, 1985; Maines, 1983; McGinn, 1976; Terman & Oden, 1947). For example, in his study of doctoral students in mathematics, Maines (1983) asked the students what they worried about. The men were most concerned about their professional status and about their mentors' estimates of their professional potential. In contrast, the women were most concerned about the impact of their graduate training on their families and their other interests; they felt that graduate training was taking too much time and energy away from other activities that they valued just as much as their graduate training. This discrepancy could reflect differing density patterns for the hierarchy of goals and personal values held by these men and women. That is, the women appeared to place high attainment value on several goals and activities; in contrast, the men appeared more likely to focus on one main goal: their professional development. If this is true, then the psychological cost of engaging in their primary goal, in terms of time and energy lost, for other important goals would certainly be less for these men than for their female colleagues.

Gender role socialization could lead males and females to place different value on various long range goals and adult activities. The essence of gender roles (and of social roles in general) is that they define the activities that
are central to the role. In other words, they define what one should do with one's life in order to be successful in that role. If success in one's gender role is a central component of one's identity, then activities that fulfill this role should have high value and activities which hamper efforts at successfully fulfilling one's gender role should have lower subjective value. Gender roles mandate different primary activities for men and women. Women are supposed to support their husbands' careers and raise their children; men are supposed to compete successfully in the occupational world in order to confirm their masculinity and to support their families. To the extent that a gifted woman has internalized this culture's definition of the female role, she should rank order the importance of various adult activities differently than her gifted male peers. In particular, she should rate the parenting and the spouse-support roles as more important than a professional career role and she should be more likely than her gifted male peers to resolve life's decisions in favor of these family roles. Kerr (1985) provides extensive documentation of this dynamic operating in the lives of today's gifted women. In contrast, gifted men, like men in general, should rate family and career roles as equally important. In fact, since they can fulfill their family role by having a successful career, gifted men, like men in general, should expect these two sets of roles to be compatible. Consequently, aspiring after a high status, time consuming career should not pose less of a conflict for gifted men and such careers should have high subjective value not only because of the rewards inherent in these occupations but also because they fulfill the male gender role mandate.

Similarly, gender roles can influence the definition one has of successful performance of those activities considered to be central to one's identity. Consequently, men and women may differ in their conceptualization of the requirements for successful task participation and completion. If so, then men and women should approach and structure their task involvement differently even when they appear on the surface to be selecting a similar task. The parenting role provides an excellent example of this process. If males define success in the parenting role as an extension of their occupational role, then they may respond to parenthood with increased commitment to their career goals and with emphasis on encouraging competitive drive in their children. In contrast, if women define success in the parenting role as high levels of involvement in their children's lives, they may respond to parenthood with decreased commitment to their career goals. Furthermore, if staying home with her children and being psychologically available to them most of the time are central components of a gifted woman's gender-role schema, then involvement in a demanding, high-level career should have reduced subjective value precisely because it conflicts with a more central component of her identity. Kerr (1985) provides compelling examples of how this process influences the career related decisions of today's gifted women--many of whom choose to limit their career development in order to do the best job they can being a wife and mother.

The analysis developed in this section suggests that the educational and occupational differences between gifted men and women result, in part, from sex differences in gender-role definition and in the structure of one's hierarchy of values and interests. These differences are assumed to be the result of differential socialization experiences and the internalization of culturally defined, and readily observable, gender roles. More specifically, this analysis suggests that the differential involvement of gifted men and women in math- and physical science-related occupations may result, in part, from differences in their interest patterns and their personal values (for example, being thing-oriented versus being person-oriented). Furthermore, this analysis suggests that the differential involvement of gifted men and women in high status, time-consuming occupations requiring long periods of preprofessional training may result, in part, from differences in men's and women's psychological investments in their family roles versus their professional roles. These gender differences in psychological investment in family versus professional roles are assumed to result from a complex set of both psychological and sociological forces including the internalization of gender roles, the individual's assessment of what jobs and roles are realistically available, and both overt and subtle forms of discrimination operating in educational and occupational institutions. Consequently, women may choose to limit their investment in the professional role because they want to maximize their
investment in their family roles or because they think that their opportunities in the professional role are restricted by discriminatory forces beyond their control, or both.

An adequate test of these hypotheses requires not only the demonstration of a sex difference on interest patterns and value hierarchies; it also requires a demonstration of the proposed causal link between these beliefs and the educational and vocational choices gifted men and women make. By and large, these causal links have not been assessed in either gifted or more typical populations. Thus, as was true for expectations of success, the essential research has yet to be done. However, even though the causal relationships implicit in this analysis have not been adequately studied, several large scale studies of the gifted have assessed sex differences in personal values and interests. In general, the data are consistent with the analysis in this section. The details of these studies are outlined below.

Sex Differences in the Values and Interests of the Gifted

Both the Terman study and the SMPY studies have assessed interests, values, and goals on a large number of gifted individuals. These studies suggest that gifted boys and girls have different interests, values, and goals from an early age. Although gifted boys and girls appeared more similar in their values and interests than comparison groups of boys and girls drawn from the general population, the gifted girls in both studies had more stereotypically feminine interest patterns than the gifted boys. When asked their favorite school subjects the girls rated English, foreign languages, composition, music, and drama higher than the boys; in contrast the boys rated the physical sciences, physical training, U.S. history, and sometimes mathematics higher than the girls (Benbow & Stanley, 1984; George & Denham, 1976; Terman, 1926, 1930). The sex differences in interest in mathematics were typically quite weak, if present at all. In contrast, the sex differences in interest in physics and applied mathematical fields like engineering are quite consistent and fairly large (Benbow, 1988; Benbow & Minor, 1986).

Similarly, when asked their occupational interests and/or anticipated college major, girls rated domestic, secretarial, artistic, biological science, and both medical and social service occupations and training higher than the boys, while the boys expressed more interest than the girls in both higher-status and business-related occupations in general, and in the physical sciences, engineering, and the military, in particular (Benbow & Stanley, 1984; Fox, Pasternak, & Peiser, 1976; Terman, 1926, 1930). Finally, when asked, their leisure time activities and hobbies, similar differences in interest patterns emerged. At all ages, the females both liked and reported spending more time than the boys reading, writing, and participating in a variety of activities related to arts and crafts, domestic skills, and drama; in contrast, the males spend more time engaged in sports, working with machines and tools, and involved with scientific, math-related, and/or electronic hobbies (Dauber & Benbow, 1990; Fox, 1976; McGinn, 1976; Terman, 1926, 1930; Terman & Oden, 1947). It should be noted, however, that some very recent studies suggest that some of these differences may be changing. Dolny (1985) has found that the gifted female high school students in Toronto, Canada, were more likely than their gifted male peers to express an interest in a professional career. How these females actually develop remains to be seen.

We have also found clear evidence of gender differences in the value attached to various school subjects and activities among elementary school aged children enrolled in a gifted program (see Table 5). The girls expressed less interest in math than the boys; they reported liking it less and also felt it was less useful than did the boys. The boys also attached greater importance to sports and felt their parents attached more importance to their participating in sports than did the girls. Finally, the boys indicated that they felt their parents attached more importance to their learning new things than did the girls. In contrast, the girls attached more importance to playing a musical instrument than the boys and felt that their parents also placed more importance in this domain.
Gender-role stereotypic patterns of differences also emerged on tests of personal values, occupational values, and personality traits. The Allport-Vernon-Lindsey Scale of Values was given to many of the children participating in the studies at Johns Hopkins. The gifted girls typically scored higher than the gifted boys on the scales tapping social and aesthetic values; in contrast, the boys typically scored higher than the girls on the scales tapping theoretical, economic, and political values (Fox, 1976; George & Denham, 1976; McGinn, 1976). Similarly, on the Strong-Campbell Vocational Interest test, the girls scored higher than the boys on social and aesthetic interests. Both of the boys and girls, however, scored equally high (and quite high) on investigative interests (Fox, Pasternak, & Peiser, 1976; George & Denham, 1976; McGinn, 1976).

It is also of interest to note that the boys evidenced a more unidimensional set of interests than the girls on the Strong-Campbell Vocational Interest test; that is, the boys scored high on investigative interests and low on most other interests. In contrast, the girls scored higher than average on several interest clusters (McGinn, 1976). A similar discrepancy emerged when gifted boys and girls were asked to rate several occupations on a Semantic Differential Scale. The boys gave positive ratings only to traditional male scientific and mathematical professions; the female professions and homemaker role were rated negatively. In contrast, the girls gave both male and female typed professions a positive rating. In addition, they gave the homemaker role as positive a rating as their most preferred professional occupations; in contrast, the gifted boys responded rather negatively to the homemaker role.

A similar pattern emerged on a recent wave of data collected from the Terman sample (Sears, 1979). The gifted men and women were asked to rate how important each of six goals were to them in making their life plans during early adulthood. Men rated only one area (occupation) as having had higher importance than did the women; in contrast, the women rated four areas as having had higher importance than did the men (family, friends, richness of one's cultural life, and joy in living). These data suggest that the gifted women had desired a more varied or multifaceted type of life than the men had desired at precisely the time in one's life when people make the major decisions about their life plans. One other pattern characterized the responses of these gifted men and women: Consistent with our hypothesis, the men rated family and occupation as of equal importance while the women rated family as more important than occupation.

The role of conflict between gender roles and achievement in gifted girls' lives is perhaps best illustrated by a recent ethnographic study of a group of gifted elementary school girls by Lee Anne Bell (1989). She interviewed a multi-ethnic group of third to sixth grade gifted girls in an urban elementary school regarding the barriers they perceived to their achievement in school. Five gender-role related themes emerged with great regularity: (1) concern about hurting someone else's feelings by winning in achievement contests; (2) concern about seeming to be a braggart if one expressed pride in one's accomplishments; (3) over-reaction to nonsuccess experiences (apparently not being the very best is very painful to these girls); (4) concern over their physical appearance and what it takes to be beautiful; and (5) concern with being overly aggressive in terms of getting the teacher's attention. In each case, the gifted girls felt caught between doing their best and either appearing feminine or doing the caring thing.

Summary

There are clear differences in the interests, values, and preferences between gifted males and females. Furthermore, these differences reflect gender-stereotyped patterns and operate in ways that limit females' educational and vocational opportunities. These results are consistent with the analysis linking values to sex differences in educational and vocational choices. Additional support for this hypothesis comes from a report by Benbow and Stanley (1982). Gifted girls in their study were less likely than gifted boys to take advanced mathematics in part because they liked language-related courses more than they liked mathematics courses. In addition, Benbow and Stanley (1984) found weak but consistent positive relations in their gifted samples between liking of biology,
chemistry, and physics and subsequent plans to major in biology, chemistry, and physics, respectively. In addition, students' interest did predict course taking in high school and college (Benbow & Minor, 1986).

Thus, although there is some support for the hypothesized impact of sex differences in values on gifted students' educational and vocational choices, this perspective has not been adequately tested. In most studies documenting the sex differences in interest patterns, personal values, and personal goals and aspirations, the mediating role of these differences in educational and vocational decisions has not been assessed. Longitudinal studies exploring the possible causal links between values and achievement-related choices are needed—work like that of Kerr (1985) using an ethnographic approach to the study of gifted women's lives would be especially useful. More information is also needed on the origin of sex differences, as well as individual differences, in values.

Parents, Teachers, and Counselors

Sex differences in educational and vocational choices could also result from differential socialization experiences. Several studies have documented the importance of social support from parents, teachers and counselors in lives of women who make nontraditional educational and occupational choices (Barnett & Baruch, 1978; Casserly, 1980; Frieze & Hanusa, 1984; Helson, 1980; Humphreys, 1984; Kerr, 1985). Perhaps gifted girls make traditional educational and occupational choices because they are not adequately encouraged to consider alternative choices. How might parents, teachers, and counselors affect gifted children's vocational and educational choices?

1. Through their power as role models. Male and female adults do different things and these differences in behavior provide a model of appropriate occupations for males and females.
2. Social agents can influence children's self-concept, personal values, and preferences through the interpretations of experience that they provide and the causal attribution they make for their children's performance on various tasks.
3. Social agents can also influence children's view of the educational and vocational world through explicit and implicit messages they provide as they "counsel" children. Social agents, especially parents and school personnel, give children information about the occupational world and the need to prepare themselves for that world. Often these messages are gender-role biased. To the extent that this is true, boys and girls will internalize different views of the occupational world, different ideas about their potential involvement in that world, and different ideas regarding the need to be able to support oneself.
4. Social agents can influence choices by the pattern of reinforcements they provide for engaging in various behaviors. Positive reinforcement will increase the likelihood that the child will engage in the activity in the future. Excessive positive reinforcements, however, can backfire and undermine the child's intrinsic motivation for engaging in the activity.
5. Social agents can influence the educational and vocational decisions of gifted individuals more directly by actively structuring the options that are offered to gifted boys and girls. For example, entry into accelerated or special programs depends on being identified as gifted by school personnel. To the extent that the process of identification is sex-biased, gifted girls and boys may differ in the opportunities they are offered to develop their skills; findings relevant to this prediction are discussed below. Parents can also either limit or broaden their children's educational and vocational options by the economic, as well as psychological, support they provide for various options. In the society at large, families with limited resources are more willing to invest these resources in their sons than in their daughters. If a similar preference characterizes families with gifted children, then gifted males should have more opportunities for special and advanced training than gifted females because their families are more willing to provide such opportunities. Such differences, if they exist, not only limit girls' options
directly; they can also limit the development of gifted girls' preferences because they restrict the range of experiences gifted girls are exposed to.

6. Finally, social agents can influence children's interest in various activities by the affective climate they create. If learning a particular skill takes place in a positive affective setting, it is likely children will come to enjoy the activity. If instead, learning a particular skill takes place in a highly charged negative affective setting, it is likely that the children will develop an aversion to the activity.

Peers can take part in each of these processes. Students discuss the options they are considering with their friends; these discussions inform the students both of the opinions of their peers and of the likely reactions their peers will have to various options. As is true for other social agents, these opinions and reactions are often gender-role biased (see, for example, Bell, 1989; Frieze & Hanusa, 1984; Kavrell & Petersen, 1984; Kerr, 1985). Since peer acceptance is so important during the adolescent years (Kavrell & Petersen, 1984), the gender-role bias in adolescents' reactions to each other's plans may limit the educational and vocational options considered seriously by gifted females at a time when very important achievement-related decisions are being made. Fear of peer disapproval could also lead gifted girls to either drop out of or refuse to participate in special programs for the gifted.

Now let's look at the research related to these types of influence. I'll begin with noting that very little information is available, and what is available is quite limited in its scope and reliability. For example, some of the work claiming to show that gender differences among the gifted do not result from differences in boys' and girls' social experiences is based on a few self-report questionnaire items asking things like "Do you encourage your child to do well in math?" This type of question does not provide an adequate assessment of social experience.

Parents

Figure 2 illustrates a model of translating the mechanisms outlined above into a systematic format that guides research. In this model, we have outlined what we think are the critical constructs in understanding possible parental influences on children's developing self-concepts and interests. Unfortunately, very little research has been done on most of these constructs. The little that exists is summarized below. We have included results from our recent study of gifted elementary school age children. In this study, we had the parents of all of the children fill out an extensive questionnaire focused on many of the constructs outlined on Figure 2. We are just beginning our analysis of these data.

In both the Terman and the Johns Hopkins studies, the parents of gifted boys and girls believed in their children's general intellectual talents. The child's sex, however, did affect the parents' estimates of their children's ability in specific domains. For example, parents in Terman's study rated the boys higher than the girls on math and mechanical ingenuity; they also rated the girls higher than the boys on drama, music and general dexterity. Since these patterns of sex differences also characterized the children's performance on standardized skill tests, we cannot determine the direction of causality for these data; the parents' estimates may have been a reflection of the differences they were observing in their children or the parents may have helped to create the behavioral differences through differential socialization practices (Terman, 1926).

We also found substantial sex of child effects on parents' beliefs and parents' behavior in the domains of reading, sports, and instrumental music. These results are summarized on Figures 3 - 6. The parents' beliefs and behaviors favored girls in the domains of reading and music. In these domains, parents of gifted girls had more confidence in their child's ability than parents of gifted boys. They also thought that their child had more interest in these domains than the parents of gifted boys. And, finally, they provided their child with more encouragement to engage in these domains than did the parents of gifted boys. In contrast, the parents of gifted boys had more
favorable beliefs and behaviors in the domain of sports than the parents of gifted girls. They rated their child as having greater interest in the domain and did more to encourage their child to participate in sports than did the parents of gifted girls.

Gender-role bias in parental beliefs is more clear on other measures. Parents in the Johns Hopkins' studies were asked their occupational aspirations for their children. These parents had rather limited occupational aspirations for their daughters; the majority of the parents of girls (between 89 and 94 percent in one study) expected their daughters to follow the traditional female-occupational pattern of working for a while and then taking time out to raise their children (Brody & Fox, 1980; Fox, 1982). The parents were also more likely to expect their sons to enter math-related or scientific fields (Brody & Fox, 1980) and to provide their sons with math- and science-related toys, kits, and books (Astin, 1984). Finally, parents of daughters reported noting giftedness in their child at a later age than parents of sons (Fox, 1982) and were often quite surprised when informed that their daughter might be gifted (Fox, personal communication, 1978). Thus, although parents have a generally positive attitude toward their daughters' intellectual talents, they do not appear to be encouraging their daughters to develop these talents in occupational pursuits to the same extent that parents of boys do.
Finally, there is clear evidence that mothers and fathers model different involvement in various academic subjects. Benbow and her colleagues have found that fathers are more likely to help their children in math and science than are mothers (Raymond & Benbow, 1989). This difference in parental behavior could influence the boys' and girls' interest in the sciences.

**Teachers and Counselors**

The data on teachers are quite mixed. On the one hand, Terman (1926, 1930) found teachers to be quite positive toward both gifted boys and girls. The teachers rated gifted girls more positively than gifted boys in terms of their performance and competence on most subjects and on deportment. In addition, boys were more often reported as being weak in at least one subject than girls. On the other hand, both Terman (1926) and Fox (1982) found that teachers were less likely to identify girls as gifted and to recommend them for accelerated educational progress. Furthermore, to the extent that teachers held negative stereotypes of gifted children, their stereotypes of gifted girls were more negative than their stereotypes of gifted boys (Solano, 1977) and they were less likely to encourage girls to consider non-traditional fields than boys. Finally to the extent that teachers treat boys and girls differently in the classroom, these differences are most marked among the brightest students in the class (Brophy & Good, 1974; Parsons, Kaczala, & Meece, 1982). These differences, however, are not found across all studies or all classrooms, and few studies have been done on the gifted in particular (Brophy & Good, 1974; Parsons, Kaczala, & Meece, 1982; Subotnik, 1991)
Both Fox (1976) and Luchins and Luchins (1980) present an even more negative picture of teachers. Fox (1976) found evidence of active resistance on the part of some teachers to continue accelerated math training for the girls who had participated in the Johns Hopkins Summer Accelerated Math Program. Furthermore, the presence or absence of teacher and counselor support for continued participation in accelerated math training was the major factor distinguishing between the girls who continued and the girls who chose to drop back into a more traditional math program. Similarly, in their study of female mathematicians, Luchins and Luchins (1980) found that 80 percent of the females, as compared to only 9 percent of the males, had encountered active discouragement from continuing their math training; this discrepancy was especially pronounced during the college years.

Evidence regarding the role of counselors is sparser but equally troublesome. In general, counselors have not been found to be especially encouraging of non-traditional educational and occupational choices for either boys or girls (see Eccles and Hoffman, 1984). A similar pattern characterizes the few available studies on the role of the counselor for gifted students. For example, counselors have been found to actively discourage gifted girls from continuing their accelerated math training program (Fox, 1976). Likewise, more than a quarter of the gifted adults interviewed by Post-Kammer and Perrone (1983) reported that their high school counseling had been poor or inadequate. Similarly, Benbow and Stanley (1982) found that less than 12 percent of gifted students they identified in their talent search were participating in any special programs; thus, the majority of gifted children are not receiving any special opportunities designed to facilitate the development of their extraordinary intellectual talent. And girls are less likely than boys to be among the few who do receive these special opportunities: For example,
only 6 percent of the girls compared to 11 percent of the boys in the Benbow and Stanley (1982) sample were in special programs.

These results are especially disturbing given the growing body of evidence that teachers and counselors can be an important source of encouragement for gifted girls. Several studies have demonstrated the positive effect of supportive teachers and well-designed classroom intervention programs on gifted and talented girls' educational and vocational plans (e.g., Brody & Fox, 1980; Callahan, 1979; Casserly, 1980; Fox, 1976; Fox, Benbow, & Perkins, 1983; Gordon & Addison, 1985; Kerr, 1985; Tomlinson-Keasey & Smith-Winberrry, 1983; Tobin & Fox, 1980; Zerega & Walberg, 1984). For example, Tomlinson-Keasey and Smith-Winberrry (1983) found a strong positive association between gifted girls' interest in high level careers and their involvement in high intensity special programs for the gifted. Casserly's (1980) work provides another clear example of this. She identified the 20 school districts in the United States that had the best record of enrollment by talented females in their Advanced Placement courses (AP courses) in math and science; she interviewed students, teachers, and counselors at these schools regarding the factors that they believed accounted for the high participation rates of the female students in these courses. Several themes emerged rather consistently across the districts: early placement in a curricular track that leads automatically to the AP courses; high proportions of females in the classes from the beginning of the tracking sequence; active efforts to allow female friends to stay together in these courses; active support by the teachers of the females' interests, confidence, and, perhaps most importantly, participation in class activities; active recruitment of younger females into the courses by the AP teachers and by female students already enrolled in the AP courses; active career counseling by AP teachers within their classes; and creative, non-competitive instruction in the AP classes.
Casserly’s study clearly suggests that supportive teachers can play an important role in encouraging gifted and talented females to develop their math and science skills and to consider seriously careers in math and science. Casserly’s study also indicates that early acceleration may be important. Several studies suggest that adolescent gifted girls are less attracted to special programs, particularly in math and science, than adolescent gifted boys (Fox, 1976; Fox, Benbow, & Perkins, 1983; Tobin & Fox, 1980). In contrast, accelerated programs begun in elementary school have as many, if not more, female participants as male participants. Furthermore, both girls and boys enrolled in such programs retain their accelerated status throughout high school and graduate at an earlier age than their non-accelerated peers without any apparent deleterious effects on their intellectual and social development (c.f. Cullahan, 1979).

Finally, Casserly’s study points to the importance of instructional strategies themselves. The AP teachers in her study were especially likely to include career counseling in their courses, to use non-competitive teaching strategies, to include applied concerns drawn from fields such as engineering, design, medicine, and architecture, to stress the creative components of math and science rather than facts and endless word problem sets, and to be actively committed to nonsexist education. Observational studies of science teachers suggest that a similar set of characteristics differentiates teachers who produce high levels of interest in science among their female students from teachers who do not (Kahle, 1983).

These studies suggest that people’s interest in a particular subject area is influenced by the way it is taught (c.f. Zerega & Walberg, 1984). If females and males come to class with different value systems and with different
Further support of the importance of these characteristics is provided by Fox (1976). Concerned with the low participation rates of gifted girls in the special program being offered at the Johns Hopkins University for gifted children, these researchers designed a special math class to attract females. This class incorporated many of the "girl-friendly" principles uncovered by Cassedy and Kohn. It was taught by females and all the students were females. The class was successful in increasing the participation rates of those gifted female students who successfully completed the program. Unfortunately, longitudinal follow-ups of these gifted female students indicate that the long range impact of this experience was minimal, suggesting that one-shot interventions are not very effective in producing lasting change and that "girl-friendly" practices need to be a continuing part of gifted girls' educational experiences (Bremn & Fox, 1990).

Learning styles, then, the same type of instruction will have different effects on females and males. These possible relationships and their link to the gender roles are outlined in Figure 7.
Conclusions

As is true in the population-at-large, gifted males and females differ in their educational and occupational patterns in a rather gender-stereotyped fashion. This chapter has explored the reasons why this might be true and outlined a research agenda to study these hypotheses. Gender-role beliefs and schema seem especially important influences in that these schema can affect both expectations for success in a wide range of activities and in the subjective value individuals attach to participation in various educational, occupational, and family-related pursuits. The beliefs and behaviors of parents, teachers, counselors, and peers are also critical. These socializers appear to lack confidence in gifted girls' ability or motivation to succeed at demanding educational programs. They do little to foster gifted girls' perceptions of these programs as valuable and important; they do little to help gifted girls evaluate the relative importance of careers and family, as well as the absolute importance of economic independence; and they do little to provide gifted girls with accurate and detailed information about the educational and occupational options available for them, and with experiences that might increase the salience of these options. Given the omnipresence of gender-role prescriptions regarding appropriate female life choices, there is little basis for gifted girls to develop non-traditional goals if their parents, teachers, and counselors do not encourage them to consider these options, and support them once they do make these choices. And there is even less basis if these socializers actively discourage such consideration.

Research reported here was sponsored by a grant from the National Institute for Child Health and Human Development to the first author. We wish to thank the following people for their help in conducting this work: Allan Wigfield, Carol Freedman-Doan, Phyllis Blumenfeld, Kwang Suk Yoon, and Amy Aberbach, as well as the school personnel and all of the families in our study.
